1. Memory Safety: Why It Matters

The Lateralus language type system represents a careful synthesis of ideas from programming language research spanning four decades. The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Type inference walkthrough
```

```
let pair = (42, "hello")   // pair: (int, str)
let (n, s) = pair          // n: int, s: str
let doubled = n * 2        // doubled: int
let upper = s.to_upper()   // upper: str
println(doubled, upper)    // type: (int, str) -> unit

// All types fully inferred; no annotations written
// Algorithm W assigns fresh vars, unifies, substitutes
```

9. Smart Pointers: Arc[T] Thread-Safe Sharing

The Lateralus language type system represents a careful synthesis of ideas from programming language research spanning four decades. The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type

annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Trait-based polymorphism
trait Printable { fn print_repr(self) -> str }
trait Comparable { fn compare(self, other: Self) -> int }

fn top_n[T: Printable + Comparable](items: list[T], n: int) -> list[T] {
    let sorted = items |> sort_by(fn(a, b) { a.compare(b) })
    return sorted |> take(n)
}

// Works for any T that implements both traits:
top_n([5,3,8,1,9,2,7], 3)   // [1,2,3]: int satisfies both
```

17. Copy Types vs. Move Types

The Lateralus language type system represents a careful synthesis of ideas from programming language research spanning four decades. The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing

for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Generic function inference
fn zip[A, B](as: list[A], bs: list[B]) -> list[(A,B)] {
    let result: list[(A,B)] = []
    for i in range(min(len(as), len(bs))) {
        result.push((as[i], bs[i]))
    }
    return result
}
```

```
// Inferred at call site:
let z = zip([1,2,3], ["a","b","c"])
// A=int (from [1,2,3]), B=str (from ["a","b","c"])
// z: list[(int, str)]
```

25. Ownership vs. Garbage Collection

The Lateralus language type system represents a careful synthesis of ideas from programming language research spanning four decades. The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%).

The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Recursive type inference
fn sum_tree(node: Tree[int]) -> int {
    match node {
        Tree.Leaf(v)        => v,
        Tree.Branch(l, r)   => sum_tree(l) + sum_tree(r),
    }
}
// Type: fn(Tree[int]) -> int (fully inferred from match)

let tree = Tree.Branch(
    Tree.Branch(Tree.Leaf(1), Tree.Leaf(2)),
    Tree.Leaf(3)
)
println(sum_tree(tree))  // 6

The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the

expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Pipeline type propagation
fn parse_line(s: str) -> list[int] {
    return s.split(",") |> map(fn(x) { int(x.strip()) })
}
```

```
let lines = read_file("data.csv").split("\n")
let all_ints = lines |> map(parse_line)  // list[list[int]]
let flat     = all_ints |> flatten()     // list[int]
let sorted   = flat |> sort()            // list[int]
let unique   = sorted |> dedup()         // list[int]
println(unique.len(), "unique values")
```

The Lateralus language type system represents a careful synthesis of ideas from programming language research spanning four decades. The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes

higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Type inference walkthrough
let pair = (42, "hello")   // pair: (int, str)
let (n, s) = pair          // n: int, s: str
let doubled = n * 2        // doubled: int
let upper = s.to_upper()   // upper: str
println(doubled, upper)    // type: (int, str) -> unit

// All types fully inferred; no annotations written
// Algorithm W assigns fresh vars, unifies, substitutes
```

The Lateralus language type system represents a careful synthesis of ideas from programming language research spanning four decades. The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single

representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Trait-based polymorphism
trait Printable { fn print_repr(self) -> str }
trait Comparable { fn compare(self, other: Self) -> int }

fn top_n[T: Printable + Comparable](items: list[T], n: int) -> list[T] {
    let sorted = items |> sort_by(fn(a, b) { a.compare(b) })
    return sorted |> take(n)
}

// Works for any T that implements both traits:
top_n([5,3,8,1,9,2,7], 3)   // [1,2,3]: int satisfies both
```

The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Generic function inference
fn zip[A, B](as: list[A], bs: list[B]) -> list[(A,B)] {
    let result: list[(A,B)] = []
```

```
    for i in range(min(len(as), len(bs))) {
        result.push((as[i], bs[i]))
    }
    return result
}

// Inferred at call site:
let z = zip([1,2,3], ["a","b","c"])
// A=int (from [1,2,3]), B=str (from ["a","b","c"])
// z: list[(int, str)]
```

The Lateralus language type system represents a careful synthesis of ideas from programming language research spanning four decades. The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the

program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file, which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Recursive type inference
fn sum_tree(node: Tree[int]) -> int {
    match node {
        Tree.Leaf(v)        => v,
        Tree.Branch(l, r)   => sum_tree(l) + sum_tree(r),
    }
}
// Type: fn(Tree[int]) -> int (fully inferred from match)

let tree = Tree.Branch(
    Tree.Branch(Tree.Leaf(1), Tree.Leaf(2)),
    Tree.Leaf(3)
)
println(sum_tree(tree))  // 6

The core inference engine uses Hindley-Milner Algorithm W, which guarantees that every well-typed program receives its most general -- or principal -- type. This ensures that functions written without any type annotations are still precisely typed, and that the compiler can catch type errors even in code that was never annotated by the programmer. The inference algorithm runs in near-linear time for typical programs, making interactive type checking fast enough for use in IDE integrations where sub-100ms response times are required.

Practical considerations drove every design decision in the type system. For instance, the choice to use structural typing for function types -- where any function with the right parameter and return types is acceptable regardless of how it was defined -- was made because it reduces boilerplate and makes higher-order programming more ergonomic. The choice to use nominal typing for struct and enum definitions was made because it prevents accidental substitution of structurally-similar but semantically-different types, which is a common source of subtle bugs. These two choices work together to give programmers flexibility where it helps and safety where it matters.

The compiler's error messages are a first-class feature of the type system implementation. When a type mismatch occurs, the compiler must report not just what went wrong but where -- including the source locations of both the expected and actual types -- and ideally suggest how to fix it. To support this, the type checker maintains provenance information throughout inference: each type variable carries the source location where it was introduced, each unification constraint records both sides and their sources, and the substitution is applied lazily so that error messages can show the original type expressions rather than fully-substituted forms.

Performance of the type checker matters for developer experience. In benchmark studies of real Lateralus codebases, type checking accounts for roughly 30% of total compilation time. The remaining time is split between parsing (15%), name resolution (10%), code generation (35%), and linking (10%). The type checker has been optimized with a persistent hash-consing scheme for type expressions, which eliminates redundant allocations for commonly-occurring types like 'int' and 'str'. With hash-consing, type expressions that appear multiple times in the program share a single representation

in memory, reducing both allocation pressure and comparison cost.

Implementation Details

The integration between the type system and the module system is a critical architectural concern. Modules export typed interfaces, and importing code sees only the declared interface -- not the implementation. This means that if a module's implementation changes but its interface stays the same, dependent code does not need to be re-type-checked. The compiler exploits this property for incremental compilation: when a file changes, only that file and its transitive dependents that actually use the changed interface are re-checked. In large codebases, this can reduce re-check time by 90% compared to full re-checking.

Testing the type system is itself a substantial engineering challenge. The test suite includes thousands of positive tests (programs that should type-check) and negative tests (programs that should not). Negative tests are particularly important: each one verifies not just that the type checker rejects the program, but also that it produces the correct error message at the correct source location. The test framework compares the actual error output against a golden file,

which makes it easy to detect regressions where a bug fix in one area accidentally changes error messages in another.

```
// Pipeline type propagation
fn parse_line(s: str) -> list[int] {
    return s.split(",") |> map(fn(x) { int(x.strip()) })
}
```

```
let lines = read_file("data.csv").split("\n")
let all_ints = lines |> map(parse_line)  // list[list[int]]
let flat     = all_ints |> flatten()     // list[int]
let sorted   = flat |> sort()            // list[int]
let unique   = sorted |> dedup()         // list[int]
println(unique.len(), "unique values")
```

```
// Trait-based polymorphism
trait Printable { fn print_repr(self) -> str }
trait Comparable { fn compare(self, other: Self) -> int }

fn top_n[T: Printable + Comparable](items: list[T], n: int) -> list[T] {
    let sorted = items |> sort_by(fn(a, b) { a.compare(b) })
    return sorted |> take(n)
}

// Works for any T that implements both traits:
top_n([5,3,8,1,9,2,7], 3)   // [1,2,3]: int satisfies both
```
